Questions 1, 2, 3, 4, 5, 6, 7, 9, 10

Question 1

a

Covariates are "supplementary variables that predict outcomes" (G & G 95). They are not required for unbiased estimation. They're used to improve precision by reducing variance in potential outcomes or differences between treatment and control observations in OLS, and to assign blocks in block randomized assignment. In theory, they are measured before subjects are randomized into treatment and control.

b

"Disturbance term" refers to the part of a regression that is unobserved, which is unexplained variation in untreated and treated outcomes.

c

Equation 4.2 demonstrates that rescaling the outcome by subtracting a pretest leads to unbiased estimates of the ATE. Subtracting the rescaled pretest cX_j instead of the pre-test X_i would. . . .(show it produces unbaised estiamtes of the ATE).

Equation 4.2 says

$$E(A\hat{T}E) = E[Y_i - X_i|D_i = 1] - E[Y_i - X_i|D_i = 0]$$

The rescaled pretest cX_i where c is constant and positive can be substituted for X_i.

$$E(A\hat{T}E) = E[Y_i - cX_i|D_i = 1] - E[Y_i - cX_i|D_i = 0]$$

So when we expand as in 4.2:

$$E(A\hat{T}E) = E[Y_i|D_i = 1] - E[cX_i|D_i = 1] - E[Y_i|D_i = 0] + cE[X_i|Di = 0]$$

. . . and rearrange:

$$E(A\hat{T}E) = E[Y_i|D_i = 1] - E[Y_i|D_i = 0] - c(E[X_i|D_i = 1] + E[X_i|Di = 0])$$

...and because we assume that the expected values of Y_i when $D_i = 0$ are the same as when $D_i = 1$, we arrive at the same place as in figure 4.2:

$$E(\hat{ATE}) = E(Y_i(1)) - E[Y_i(0)]$$

d

The slope parameter b in equation 4.7 is the change in average potential outcomes $\mu_{Y1} - \mu_{Y0}$, also called the ATE.

$$E(ATE) = E[Y_i(1)] - E[Y_i(0)]$$

e

Balanced designs are ideal because they allow for interval estimation: CI's will be conservative rather than too wide or narrow from outcome variances with imbalance in the treatment and controls that produce. They're particularly helpful when there is similar variance in the outcomes of treatment and control groups.

Question 2

a.

RI to test the null that pre-test scores are unaffected by treatment assignment.

```
data_2 <- read.csv("/Users/kom11/Documents/GitHub/regression-study/Experiments/doi-10.60600-yu-vuh8kd/G

set.seed(312608170)

names(data_2)
```

```
## [1] "subject"     "treatment"   "pretest"     "posttest"    "improvement"
```

```
subject <- data_2$subject
treatment <- data_2$treatment
pretest <- data_2$pretest
posttest <- data_2$posttest
improvement <- data_2$improvement

model_2 <- lm_robust(treatment ~ pretest)

fstat_2 <- model_2$fstatistic[1] # get the f stat of treatment

fstat_2
```

```
##    value
## 1.268712
```

```r
# now random. inference with f-stat to get a p-value:

ra_2 <- declare_ra(nrow(data_2), m = 9) # random assignment procedure

perm_matrx_2 <- obtain_permutation_matrix(ra_2) #10k randomization permmatrix

estimates_2 <- c() #bucket to store results

for (i in 1:ncol(perm_matrx_2)) {

  data_2$ri <- perm_matrx_2[, i]

  random_inf_2 <- lm_robust(data_2$ri ~ data_2$pretest)

  estimates_2 <- c(estimates_2, random_inf_2$fstatistic[1])

}
```

The reported p-value is:

```r
print(mean(estimates_2 >= random_inf_2$fstatistic))
```

```
## Warning in estimates_2 >= random_inf_2$fstatistic: longer object length is not
## a multiple of shorter object length
```

```
## [1] 0.2093
```

We can't reject the null hypothesis that treatment had no effect on pretest scores because 0.2093 is much higher than 0.05. In this case, rejecting the null means randomization was successful.

b

```r
dim_2 <- difference_in_means(posttest ~ treatment, data = data_2)
dim_ate_2 <- dim_2$coefficients
```

Treatment's effect on posttest scores is:

```r
print(dim_ate_2)
```

```
##  treatment
## -0.3333333
```

Now 95% CI constructed with randomization inference:

```r
set.seed(312608170)

null <- 0

dim_estimates_2 <- c()
```

```r
data_2 <- data_2 %>%
  mutate(
    y0_null = case_when(
      treatment == 0 ~ posttest,
      treatment == 1 ~ posttest - null
    ),
    y1_null = case_when(
      treatment == 1 ~ posttest,
      treatment == 0 ~ posttest + null
    )
  )

```

Table 1: CIs for DIM

	Est.
2.5%	-1.888889
97.5%	1.888889

c

D-i-D to estimate effect of treatment on post-test score:

```
did_2 <- difference_in_means(improvement ~ treatment, data = data_2)

did_ate_2 <- did_2$coefficients

print(did_ate_2)
```

```
## treatment
##         1
```

95% CI, and compare to interval from b.

```
#CI's from difference_in_means() function

did_ci_2 <- c(
  lower = dim_2$conf.low,
  upper = dim_2$conf.high
)

did_ci_2
```

```
##     lower     upper
## -2.523652  1.856985
```

```
knitr::kable(did_ci_2, caption = "CIs for DIM", col.names = "Est.")
```

Table 2: CIs for DIM

	Est.
lower	-2.523652
upper	1.856985

The interval is wider than for the DIM estimation of the effect of treatment on the postscore. This suggests that adjusting for the pre-test covariate with the D-i-D estimation did not lead to gains in precision, which is surprising.

Question 3

This reporting policy does not offer up unbiased estimates because it is premised on the outcomes – seems like rather explicit researcher-induced bias. Whether or not to report results based on covariates included should only be decided by theory and expectations (pre-registered, ideally, hypotheses).

Is estimated slope the same as estimated ATE based on DIM

```r
mean(data_4$obs_y [data_4$D == 0]) #control group mean should = intercept value
```

```
## [1] 26.85
```

Yes. Being assigned to treatment is associated with 10.7 higher scores compared to not being assigned to treatment.The mean value of those not assigned to treatment is 26.85 (as shown in the coefficient estimate for the Intercept and the mean value of observed ys when D is 0).

b

The condition in equation 4.6 requires that the sum of the slope coefficients from regressing treated and untreated outcomes on X_i is > 1.

Upon including the covariate, D's coefficient estimate of the treatment effect is now smaller – nearly halved. This likely is from correcting an imbalance. The SE is also smaller, suggesting we should have greater confidence in the results from this covariate adjusted model than for the no-covariate DIM.

Weights vary by 0.024 SDs in the control group and by 0.018 in the treatment group.That seems like a small difference (ie, observed variation in estimated weights is small), and otherwise they are comperable. I know we can't always assume that balance in terms of numbers in treatment and control has anything to do with covariate balance (or, equal C/T group size alone doesn't mean equal probability of being treated).Here also reversing treatment or control assignment does not change the F stat (with 20 of 40 schools treated, true probability of being treated is 0.5, so everyone's weight is 2).

The p-value of 0.0046 lets us reject the sharp null: observed treatment effect is unusual enough under the sharp null (Y1=Y0) to reject the hypothesis of no treatment effect.

Here we get a two-sided p-val of 0.0029 which is less than 0.05 (we would very infrequently generate a covariate-adjusted treatment coefficient at least as extreme as that observed if treatment had no effect) we can reject the sharp null (no effect for any school).

Sampling variability shrinks notably with covariate adjustment – it "worked."

d Sampling distribution comparison: 5 (dim_estimates_5 and coef_estimates_5c) to 4 (estimates_4 and coef_estimates_4c) (latter assumed unrestricted randomization).

The standard deviations reflect variability in estimated treatment effects across hypothetical random assignments. We see restricted randomization did reduce the SD, so "worked" in the sense that some variation the covariate would have 'controlled' was eliminated, by excluding hypothetical random assignments that would have had more of a relationship between covariates and the outcome (reduces chance covariate imbalance to sampling variability). The exclusion restriction of 0.05 might be a bit lax and only reduce extreme cases.

Comparing restricted randomization having adjustd for covariates: the difference is fairly negligible (see lefthand side of the plot above). This makes sense: regression already adjusts for pre-treatment scores, reducing whatever differences those scores would be associated with vis-a-vis estimates of treatment effects.

Perhaps the topline is restricted randomization and regression adjustment are able to address the same (or some of the same) conduits for sampling variability. At the same time, one (at least RR) doesn't eliminate the value of the other (CA).

1996 evaluations of conditions seem most strongly predicted by 1995 evaluations – the other variables do not report a significant relationship. The R^2 is 0.3937: about 39% of the variation in the 1996 evaluations is explained by our model.

c

Randomly bocking or blocking on a non-prognostic covariate does not increase precision by design. It could by accident I suppose (or would that mean blocking on a covariate that is in fact progrostic, though not known to be?) but we see here that it can instead produce identical sampling variance as that given by complete random assignment.

Question 9

```
data_9 <- read.csv("./doi-10.60600-yu-vuh8kd/Gerber_Green_AAAPSS_2005.csv")
```

a

The effect of getting phone banked on turnout was positive in Iowa districts that were not competitive. The effect was positive in the Michigan districts that were competitive, and negative in those that were non competitive. Neither was particularly pronounced.

b

The composition of treated subjects within each block and differences in block sizes are obscured in the total ATE.

c

The ATE estimated by overall Block:

```
block1 <- 0.049487*0.00964
block2 <- 0.1520981*(-0.007829)
block3 <- 0.626616*(-0.01362)
block4<-0.171799*0.008271

ate_9 <- block1+block2+block3+block4

print(ate_9)
```

```
## [1] -0.007827282
```

d

The OLS weights consider within-block balance and the size of blocks for control and treatment blocks. Balanced blocks have lower sampling variability than do imbalanced blocks, so balanced blocks are more heavily weighted. The OLS weights in 4.3 are more balanced than in part c.

We cannot reject the null: observed association between turnout and treatment assignment is not distinguishable from (or not unusually large compared to) that which randomization by precinct could have produced by chance (ie not evidence of problematic covariate imbalance). 93.7% of simulated cluster assignments produced F-stats at least as large as 1.654.

Assignment to a treated precinct is associated with an increase of 5.6 percentage poings in one's probability of voting in 2003, net of voting across the other 20 elections. The adjusted R2 suggests that 32.23% of observed variation in 2003 turnout (individual) is explained by the model containing turnout in past elections and treatment assignment.

Sharp null: Y0 = Y1. The p value for this sharp null is 0.0045 – this is less than the standard 0.05 cutoff and 0.01. Thus we can reject the null hypothesis (at both the 5% and 1% significance levels) that experimental assignment had no effect on decisions to vote in 2003 (only 0.45% of simulated random assignments under the sharp null generated treatment effects as extreme as that reported in the observed ATE.
